Abstract

We develop applications of selection functions to proof theory and computational extraction of witnesses from proofs in classical analysis. The main novelty is a translation of classical minimal logic into minimal logic, which we refer to as the *Peirce translation*, as it eliminates uses of Peirce’s law. When combined with modified realizability this translation applies to full classical analysis, i.e. Peano arithmetic in the language of finite types extended with countable choice and dependent choice. A fundamental step in the interpretation is the realizability of a strengthening of the double-negation shift via the iterated product of selection functions. In a separate paper we have shown that such a product of selection functions is equivalent, over system T , to modified bar recursion.

Keywords: Peirce’s law, negative translation, countable choice, dependent choice

1. Introduction

Negative translations, also known as double negation translations, underpin virtually all computational interpretations of classical logic, arithmetic and analysis. First introduced as a way to reduce the consistency of classical arithmetic to that of intuitionistic arithmetic, these translations have proven to be useful also in computer science [1], set theory [2], arithmetic, and analysis [3].

Most negative translations are based on the so-called *continuation monad*, which associates each type A with a new type

$$KA \equiv (A \rightarrow R) \rightarrow R.$$

Email addresses: m.escardo@cs.bham.ac.uk (Martín Escardó), paulo.oliva@eecs.qmul.ac.uk (Paulo Oliva)

When $R = \perp$ this corresponds to the double negation $\neg\neg A$ of A . In this paper we consider a different translation based on the *Peirce monad*

$$JA \equiv (A \rightarrow R) \rightarrow A.$$

We call this the Peirce monad because the algebras of J are formulas satisfying Peirce's law $JA \rightarrow A$. We have shown in [4] that the construction J over any cartesian closed category gives rise to a strong monad, with a monad morphism $\varepsilon \in JA \mapsto \phi \in KA$ from J to K as

$$\phi p = p(\varepsilon(p)). \quad (1)$$

Both J and K are strong monads, in the sense that we have morphisms

$$A \times TB \rightarrow T(A \times B),$$

for $T \in \{J, K\}$, satisfying certain equations. As a consequence of strength we also have a product operation

$$TA \times TB \rightarrow T(A \times B).$$

In previous work [4, 5], we investigated the monad J from a general perspective, and showed that the product operation corresponding to the monad J can be seen as computing optimal strategies for a general definition of sequential games (cf. [6]). We have called elements $\varepsilon \in JA$ *selection functions* for the type A , as these can be viewed as selecting an element $\varepsilon p \in A$ for any given mapping $p \in A \rightarrow R$. In the concrete case when R is the set of booleans \mathbb{B} , if ε always selects $x = \varepsilon p$ such that $p(x)$ holds, whenever that is possible, this corresponds to Hilbert's ε -operator in his ε -calculus. Moreover, as in the ε -calculus one can define the existential quantifier from the ε -terms, we can also view elements of KA as *quantifiers*. Equation (1) says that any selection functions defines a quantifier.

In [5], the first author considered the particular case where the object A is a domain, and the object R is the domain of boolean values. The particular quantifier ϕ studied was the bounded existential quantifier \exists_S for a subset S of A , with the requirement that $\varepsilon(p)$ be an element of S such that if $p(s)$ holds for some $s \in S$, then $p(\varepsilon(p))$ holds, i.e. Equation (1), for all $p \in A \rightarrow R$. The set $S \subseteq A$ is called *exhaustible* if the quantifier $\phi = \exists_S$ is computable, and *searchable* if additionally there is a computable functional $\varepsilon \in JA$ satisfying (1). It turns out that any searchable set (of total elements) is topologically compact, and, mimicking the Tychonoff theorem from topology, it was shown that searchable sets are closed under countable products. This relies on a *countable-product functional* of type

$$(JA)^n \rightarrow JA^n \quad (n \leq \omega),$$

which can be obtained by iterating the binary product of the monad J discussed above.

In [4], we considered much more general choices for A and R (objects of a cartesian closed category), and for ϕ (e.g. supremum functional when R are the reals in the category of sets, or in suitable categories of spaces). Moreover, we considered the above product in more generality, allowing the object A to vary, i.e. having type

$$\prod_{i < n} JA_i \rightarrow J \left(\prod_{i < n} A_i \right) \quad (n \leq \omega).$$

The case $n = \omega$ is restricted to a category of continuous maps of certain spaces, which include Kleene–Kreisel spaces of continuous functionals, and requires that R be discrete (e.g. the natural numbers or more generally the types defined in [5, Definition 4.12]) to be well defined. We have shown that this iteration is an instance of the bar recursion scheme. In [7] we have established relations between this new form of bar recursion and the more traditional instances, such as Spector’s bar recursion [3] and modified bar recursion [8, 9].

In the present paper we interpret the objects A and R as logical formulae, and the morphisms as proofs in intuitionistic or minimal logic, or as computable realizers of entailments. For $T = J$ or $T = K$, or more generally any strong monad T , one has the intuitionistic laws

$$\begin{aligned} T(A \rightarrow B) &\rightarrow TA \rightarrow TB && \text{(functor)} \\ A &\rightarrow TA && \text{(unit)} \\ TTA &\rightarrow TA && \text{(multiplication)} \\ A \wedge TB &\rightarrow T(A \wedge B) && \text{(strength)}. \end{aligned}$$

In the terminology of [2], the construction T is a lax modal operator. It turns out that the infinite product of selection functions realizes, in the sense of modified realizability, the following shift principle for $T = J$, assuming that R has a discrete type of realizers:

$$T\text{-shift} \quad : \quad \forall n TA(n) \rightarrow T\forall n A(n).$$

The well-known double negation shift is the case $T = K$ with $R = \perp$, but it is realized only for special types of formulae A , including those in the image of the negative translation, whereas the J -shift is realized for *all* formulae A . We also show that the double negation shift for formulas A in the image of a negative translation follows from the J -shift. With this, we will get an alternative way of interpreting classical analysis and extracting computational witnesses via infinite products of selection functions.

This is a journal version of the paper [10]. We have improved the formulation and expanded several passages of the conference version, as well as included all proofs and the new Section 7 on weak König's lemma.

2. Preliminaries

2.1. Products of Selection Functions

As mentioned above, we use the infinite product of selection functions to interpret the classical countable and dependent choice. In this section we briefly recall these product functionals which were first defined and studied in [4, 7].

Definition 2.1 (Products of selection functions) *Given selection functions $\varepsilon \in JX$ and $\delta \in JY$, define their product $\varepsilon \otimes \delta \in J(X \times Y)$ as*

$$(\varepsilon \otimes \delta)(p) = (a, b(a))$$

where

$$a = \varepsilon(\lambda x.p(x, b(x)))$$

$$b(x) = \delta(\lambda y.p(x, y)).$$

Similarly, given $\varepsilon \in JX$ and a family of selection functions $\delta \in X \rightarrow JY$, define their dependent product $\varepsilon \otimes_d \delta \in J(X \times Y)$ as

$$(\varepsilon \otimes_d \delta)(p) = (a, b(a))$$

where

$$a = \varepsilon(\lambda x.p(x, b(x)))$$

$$b(x) = \delta(x)(\lambda y.p(x, y)).$$

We have also considered in [4] the functional obtained by iterating these binary products on an infinite sequence of selection functions.

Definition 2.2 (Iterated products of selection functions) *Let $\varepsilon \in \prod_{k \in \mathbb{N}} JX_k$. The iterated product of selection functions is defined in [4] by the equation*

$$\mathbf{ps}_k(\varepsilon) \stackrel{J(\prod_{i \geq k} X_i)}{\cong} \varepsilon_k \otimes (\mathbf{ps}_{k+1}(\varepsilon)).$$

For $\varepsilon: \prod_{k \in \mathbb{N}} (\prod_{j < k} X_j) \rightarrow (JX_k)$ and $s: \sum_{k \in \mathbb{N}} (\prod_{j < k} X_j)$, define the iterated dependent product of selection functions as

$$\mathbf{PS}_s(\varepsilon) \stackrel{J(\prod_{i \geq k} X_i)}{\cong} \varepsilon_s \otimes_d (\lambda x^{X_k}. \mathbf{PS}_{s*x}(\varepsilon)).$$

The recursive definitions for \mathbf{ps} and \mathbf{PS} uniquely define functionals in the models of partial and total continuous functionals (cf. [4]). Finally, we remark that \mathbf{ps} and \mathbf{PS} are actually inter-definable over system T , as shown in [7].

2.2. Formal Setting

Let ML stand for *minimal logic*, i.e. intuitionistic logic without the ex-falso-quodlibet axiom scheme $\text{EFQ}: \perp \rightarrow A$ (see e.g. [11]). We denote by HA the formal system of Heyting arithmetic based on minimal logic, rather than intuitionistic logic. Given a formal system S we write S^ω for the finite type generalisation of S with a neutral treatment of equality (cf. [12]). Hence, Heyting arithmetic in all finite types is denoted by HA^ω . We use X, Y, Z for variables ranging over finite types.

Let us denote by *T-logic* the extension of ML with the *T-elimination axiom*

$$T\text{-elim} \quad : \quad TA \rightarrow A.$$

As such, classical logic amounts to *K-logic* if we choose $R = \perp$ in the definition of *K*. Similarly, we refer as *T-arithmetic* (TA) to the extension of HA with the *T-elimination axiom*. Then Peano arithmetic (PA) is *K-arithmetic* for $R = \perp$.

Although in HA^ω one does not have dependent types, we will develop the rest of the paper working with types such as $\prod_{i \in \mathbb{N}} X_i$ rather than the special case X^ω , when all X_i are the same. The reason for this generalisation is that all results below go through for the more general setting where this simple form of dependent type is permitted. Nevertheless, we hesitate to define a formal extension of HA^ω with dependent types, leaving this to future work.

We often write $\prod_i X_i$ for $\prod_{i \in \mathbb{N}} X_i$. If x has type X_n and s has type $\prod_{i < n} X_i$ then $s * x$ is the concatenation of s with x , which has type $\prod_{i \leq n} X_i$. When $x: X_0$ and $\alpha: \prod_{i > 0} X_i$ then $x * \alpha$ is the concatenation of x with the stream α , which has type $\prod_i X_i$. Moreover, $[\alpha](n)$ stands for the initial segment of the infinite sequence α of length n , i.e.

$$[\alpha](n) = \langle \alpha(0), \alpha(1), \dots, \alpha(n-1) \rangle.$$

For a fixed formula R , we write $J_R A$ for $(A \rightarrow R) \rightarrow A$, i.e. the selection functions for A . Using this notation, the usual Peirce's law corresponds to the principle of *J-elimination*

$$\text{PL}_R \quad : \quad J_R A \rightarrow A.$$

We first observe that the construction $J_R A$ has the same properties as that of a strong monad (from category theory).

Lemma 2.3 (Monad) *The following are provable in ML*

$$(i) \quad A \rightarrow J_R A$$

$$\begin{array}{c}
\frac{[A \rightarrow B]_\beta \quad [A]_\alpha}{\frac{B}{R} \text{ (I)}} \\
\frac{\frac{B}{R} \text{ (I)}}{(A \rightarrow B) \rightarrow R} \text{ (\beta)} \\
\frac{(A \rightarrow B) \rightarrow R}{A \rightarrow B} \text{ (III)} \quad [A]_\alpha \quad \frac{[A \rightarrow B]}{A \rightarrow R} \text{ (I)} \\
\frac{[A \rightarrow B]}{A} \text{ (II)} \\
\frac{\frac{B}{R} \text{ (I)}}{A \rightarrow R} \text{ (\alpha)} \quad \frac{\frac{B}{R} \text{ (I)}}{(A \rightarrow B) \rightarrow R} \text{ (III)} \\
\frac{A \rightarrow R}{A} \text{ (II)} \quad \frac{(A \rightarrow B) \rightarrow R}{A \rightarrow B} \text{ (III)} \\
\hline
B
\end{array}$$

Figure 1: Derivation of Lemma 2.3 (iii)

(ii) $J_R J_R A \rightarrow J_R A$

(iii) $J_R(A \rightarrow B) \rightarrow J_R A \rightarrow J_R B$.

Proof All can be proved directly. Point (i) follows by weakening, while point (ii) makes use of three contractions over $A \rightarrow R$. The proof of (iii) is a bit trickier so we spell out the details here: Assume (I) $B \rightarrow R$ and (II) $J_R A$ and (III) $J_R(A \rightarrow B)$, we derive B as shown in Figure 1. \square

2.3. Bar induction and continuity

Several proofs in the paper rely on two non-classical principles which we state here: The principle of *continuity*

$$\text{CONT} : \forall q^{\Pi_i X_i \rightarrow R} \forall \alpha \exists n \forall \beta ([\alpha](n) \stackrel{X_n}{\equiv} [\beta](n) \rightarrow q(\alpha) \stackrel{R}{\equiv} q(\beta))$$

with R discrete, and the scheme of *relativised quantifier-free bar induction* BI

$$\left\{ \begin{array}{c} Q(\langle \rangle) \\ \wedge \\ \forall \alpha \in Q \exists n P([\alpha](n)) \\ \wedge \\ \forall s \in Q (\forall x [Q(s * x) \rightarrow P(s * x)] \rightarrow P(s)) \end{array} \right\} \rightarrow P(\langle \rangle),$$

where $Q(s)$ is an arbitrary predicate, $P(s)$ a quantifier free predicate in the language of HA^ω , and $\alpha \in Q$ and $s \in Q$ are shorthands for $\forall n Q([\alpha](n))$ and $Q(s)$ respectively.

3. T -translation

It is well known that several forms of the negative translation can be understood in terms of the continuation monad K . It is also well known that any monad T gives rise to a proof translation (see e.g. [2]). Here we consider the T -translation inductively defined as

$$\begin{aligned}
P^T &= TP \\
(A \wedge B)^T &= A^T \wedge B^T \\
(A \vee B)^T &= T(A^T \vee B^T) \\
(A \rightarrow B)^T &= A^T \rightarrow B^T \\
(\exists x A)^T &= T(\exists x A^T) \\
(\forall x A)^T &= \forall x A^T.
\end{aligned}$$

That is, we prefix T in front of atomic formulae, disjunctions and existential quantifications. For $T = K$ and $R = \perp$, this amounts to the standard Gödel-Gentzen negative translation [11], and for $R = A$, with A a Σ_1^0 -formula, this corresponds to Friedman's A -translation [13] of the negative translation.

From well-known properties of monads on cartesian closed categories, one sees by induction that any C in the image of the T -translation is a T -algebra and in particular $TC \rightarrow C$ is provable. Putting all this together we have that $TC \rightarrow C$ is provable in minimal logic, for formulae C in the image of the T -translation. For $T = K$ and $R = \perp$ the T -elimination principle $TC \rightarrow C$ amounts to double negation elimination. For $T = J$ this is the instance $((C \rightarrow R) \rightarrow C) \rightarrow C$ of Peirce's law, and hence we also refer to the J -translation as the *Peirce translation*.

Because of the monad morphism $J \rightarrow K$, any K -algebra is a J -algebra, which gives the standard fact that the usual negative translations also eliminate Peirce's law. Notice that the implication $JA \rightarrow KA$ can be reversed if and only if $R \rightarrow A$. In fact, a main difference between the K -translation and the J -translation is that the former also eliminates ex-falso-quodlibet EFQ ($\perp \rightarrow A$), whereas the latter is sound with respect to EFQ but does not eliminate it.

The following facts are well known (see e.g. [2]) and are easily proved by induction on formulae, although they are usually stated for intuitionistic logic rather than minimal logic.

Lemma 3.1 *For any strong monad T , assuming that $(TA)^T = TA^T$, we have*

1. $\text{ML} \vdash TA^T \rightarrow A^T$.
2. $\text{ML} + T\text{-elim} \vdash A^T \rightarrow A$.

3. $\text{ML} + T\text{-elim} \vdash A$ if and only if $\text{ML} \vdash A^T$.

The above lemma allows one to extract realizing functions for Π_2^0 -theorems in minimal arithmetic with Peirce's law without ever going through intuitionistic logic. We will see later that the main obstacle for a realizability interpretation of classical logic is the EFQ, which says that a realizer for falsity must be turned into a realizer for an arbitrary formula. That forces all negated formulas to be empty of realizers and hence blocks any direct use of realizability to proofs in classical logic. The well-known remedy is to use Friedman's trick of the A -translation, which effectively eliminates EFQ and hence allows one to inject computational content into negated formulas. The next theorem shows that Friedman's trick is not necessary if one starts with a classical proof that does not make use of EFQ.

Theorem 3.2 *Assume that $P(x, y) \rightarrow R$ and that the variable y is not free in R . If*

$$\text{ML} + J\text{-elim} \vdash \forall x \exists y P(x, y)$$

then also

$$\text{ML} \vdash \forall x \exists y P(x, y).$$

Proof First notice that under the assumption $P(x, y) \rightarrow R$ we have

- (i) $\text{ML} \vdash JP(x, y) \rightarrow P(x, y)$,
- (ii) $\text{ML} \vdash J\exists y P(x, y) \rightarrow \exists y P(x, y)$.

If $\text{ML} + J\text{-elim} \vdash \forall x \exists y P(x, y)$ then $\text{ML} + J\text{-elim} \vdash \exists y P(x, y)$, and hence Lemma 3.1 gives $\text{ML} \vdash J\exists y JP(x, y)$, which by (i) and (ii), implies that $\text{ML} \vdash \exists y P(x, y)$. \square

The first part of the next proposition shows that if multiple instances of J -elimination are used in a proof, for different parameters R , one can reduce to a single instance with the conjunction of all the parameters. For example, this can be applied to the above theorem if one needs to use several instances of Peirce's law. The second part shows that the J - and K -translations coincide over intuitionistic logic.

Proposition 3.3

- 1. $\text{ML} + J_{R_0 \wedge R_1}\text{-elim} \vdash J_{R_0}\text{-elim} \wedge J_{R_1}\text{-elim}$.
- 2. For $R \equiv \perp$ we have that $\text{ML} + \text{EFQ} \vdash A^K \leftrightarrow A^J$.

Proof The first part is routine verification. The second part follows from Proposition 4.2. \square

Putting Theorem 3.2 and Proposition 3.3 together with obtain:

Corollary 3.4 *Assume $P(x, y) \rightarrow R_i$, for all $0 \leq i \leq n$, with $y \notin \text{FV}(R_i)$. If*

$$\text{ML} + \text{PL}_{R_0} + \dots + \text{PL}_{R_n} \vdash \forall x \exists y P(x, y)$$

then also

$$\text{ML} \vdash \forall x \exists y P(x, y).$$

Proof Let $R \equiv R_0 \wedge \dots \wedge R_n$. First note that $P(x, y) \rightarrow R_i$ implies $P(x, y) \rightarrow R$ and hence both (over ML)

$$(i) \ J_R P(x, y) \rightarrow P(x, y)$$

$$(ii) \ J_R \exists y P(x, y) \rightarrow \exists y P(x, y).$$

Assuming $\text{ML} + \text{PL}_{R_0} + \dots + \text{PL}_{R_n} \vdash \forall x \exists y P(x, y)$ by Lemma 3.3 we get $\text{ML} + \text{PL}_R \vdash \exists y P(x, y)$. Theorem 3.1 then implies $\text{ML} \vdash J_R \exists y J_R P(x, y)$, which by (i) and (ii) implies that $\exists y P(x, y)$ is provable in ML. \square

3.1. Arithmetic

If a formula does not have occurrences of disjunction or existential quantification, its T -translation only prefixes T to atomic formulae, and hence the T -translations of the Peano axioms follow from the Peano axioms. Moreover, the T -translation of each instance of the induction axiom is again an instance of induction. This shows that the T -translation maps TA into HA.

4. Countable Choice and Shift Principles

Contrary to arithmetic, discussed just above, the T -translation does not map $\text{TA}^\omega + \text{AC}_\mathbb{N}$ into $\text{HA}^\omega + \text{AC}_\mathbb{N}$, where $\text{AC}_\mathbb{N}$ is the axiom of countable choice

$$\text{AC}_\mathbb{N} \quad : \quad \forall n^\mathbb{N} \exists x^X A(n, x) \rightarrow \exists f \forall n A(n, fn),$$

and this failure applies to the particular cases $T = J$ and $T = K$ too. In fact, the T -translation of $\text{AC}_\mathbb{N}$ is

$$\text{AC}_\mathbb{N}^T \quad : \quad \forall n T \exists x A^T(n, x) \rightarrow T \exists f \forall n A^T(n, fn),$$

which is not an instance of $\text{AC}_\mathbb{N}$. In order to overcome this, the following was first observed by Spector [3] for the special case $T = K$ and $R = \perp$, where

$$T\text{-shift}(A) \quad : \quad \forall n^\mathbb{N} T A(n) \rightarrow T \forall n A(n).$$

Proposition 4.1 $AC_{\mathbb{N}} + T\text{-shift} \vdash AC_{\mathbb{N}}^T$.

Proof Let us show that $HA^{\omega} + AC_{\mathbb{N}} + T\text{-shift} \vdash AC_{\mathbb{N}}^T$. Applying T -shift to the premise $\forall n T \exists x A^T(n, x)$ of $AC_{\mathbb{N}}^T$, we deduce that $T \forall n \exists x A^T(n, x)$. Functoriality of T applied to $AC_{\mathbb{N}}$ with A instantiated to A^T gives

$$T \forall n \exists x A^T(n, x) \rightarrow T \exists f \forall n A^T(n, fn),$$

and hence we get $T \exists f \forall n A^T(n, fn)$ by modus ponens, which is the conclusion of $AC_{\mathbb{N}}^T$. \square

It follows from Lemma 3.1 and Proposition 4.1 that the T -translation maps the theory $TA^{\omega} + AC_{\mathbb{N}}$ into $HA^{\omega} + AC_{\mathbb{N}} + T\text{-shift}$. In the context of the dialectica interpretation, Spector showed that a form of bar recursion, now known as *Spector bar recursion*, realizes the *double negation shift* (DNS), which amounts to the T -shift for $T = K$ and $R = \perp$. Moreover, via different forms of bar recursion with R a Σ_1^0 formula, it is shown in [8, 9] how computational information can also be extracted via (modified) realizability from proofs in classical analysis in the presence of countable choice. But the K -shift is established only for formulae $\exists x A^K$ where A^K is in the image of the K -translation. Now notice that for any formula A^K we have $\perp \rightarrow \exists x A^K$.

Proposition 4.2 *Over minimal logic, if $R \rightarrow A$ then $J\text{-shift}(A) \rightarrow K\text{-shift}(A)$.*

Proof We know that $JA \rightarrow KA$ for any A , and the assumption $R \rightarrow A$ is easily seen to give the converse, and hence $JA \leftrightarrow KA$. Notice that if $KA \rightarrow JA$ holds then $R \rightarrow A$, and hence the assumption $R \rightarrow A$ is optimal. \square

Hence the following gives an alternative way of realizing the K -shift for the purposes of extracting witnesses from classical proofs with countable choice. The notions in the assumptions of the following theorem are defined in [9, 12].

Theorem 4.3 ($HA^{\omega} + BI + \text{CONT}$) *If R has a discrete type of realizers, then $\text{ps}_0 \text{mr } J\text{-shift}(A)$.*

Proof We fully prove a stronger result in Section 6.2. \square

The restriction on R is needed for the infinite product to be well-defined [4], and notice that it is fulfilled if R is Σ_1^0 or a Harrop formula. We emphasise that the above theorem states that the infinite product functional *itself* realizes the shift principle. This is in contrast with the work discussed above, where the bar recursive functionals in question are *used in order to define* functionals that realize shift principles, but do not realize the shift principles themselves as they do not have the required types.

We regard as rather striking the fact that a functional that was originally introduced to mimic a theorem from topology in a computational setting, as discussed

in the introduction, turns out to have a natural logical reading related to traditional work in proof theory, and we think that this deserves further investigation. In summary, the J -shift can be seen as a logical analogue of the Tychonoff theorem from topology.

Before moving to the treatment of dependent choice, let us observe that the following apparent generalisation of the T -shift is equivalent over HA to the original formulation.

Proposition 4.4 *The T -shift principle is equivalent to the course-of-values T -shift*

$$T^c\text{-shift}(A) \quad : \quad \forall n(\forall k < n A(k) \rightarrow TA(n)) \rightarrow T\forall n A(n).$$

Proof It is straightforward that T^c -shift implies the T -shift. Conversely, assume $\forall n(\forall k < n A(k) \rightarrow TA(n))$. By the extension law $(B \rightarrow TC) \rightarrow (TB \rightarrow TC)$ of strong monads in a cartesian closed category and induction on n , we deduce that $\forall n(\forall k < n TA(k) \rightarrow TA(n))$. Hence $\forall n TA(n)$ by course-of-values induction, and the T -shift gives the desired result. \square

The reason we formulate this course-of-values variant of T -shift is because T^c -shift is directly realizable by the iteration of the dependent product PS.

Theorem 4.5 ($\text{HA}^\omega + \text{BI} + \text{CONT}$) *If the formula R has a discrete type of realizers then $\text{PS}_\diamond \text{mr } J^c\text{-shift}(A)$.*

In Section 6.2 we show that PS in fact also realizes a more general logical principle that implies full dependent choice. But first, let us discuss the simpler case of dependent choice for numbers.

5. Dependent Choice for \mathbb{N}

We now compare TA^ω and HA^ω with respect to the axiom of *dependent choice*

$$\text{DC}_X \quad : \quad \forall n^\mathbb{N}, x^X \exists y^X A_n(x, y) \rightarrow \forall x_0 \exists \alpha (\alpha_0 = x_0 \wedge \forall n A_n(\alpha_n, \alpha_{n+1})).$$

In this section we focus on the simpler case when $X = \mathbb{N}$. In Section 6.2 below we consider the general case.

Proposition 5.1 $\text{DC}_\mathbb{N} + T\text{-shift} \vdash \text{DC}_\mathbb{N}^T$.

Proof The argument is essentially the same as that of Proposition 4.1, but one applies the T -shift twice, to move T outside two numerical universal quantifiers. \square

Hence, the T -translation maps $\text{TA} + \text{DC}_{\mathbb{N}}$ into $\text{HA} + \text{DC}_{\mathbb{N}} + T$ -shift. In general, however, when X is an arbitrary type, not just \mathbb{N} , the situation is subtler, because the T -shift will not be available for $T = J$ (let alone $T = K$). The case $T = K$ has been addressed in [8, 9], and in Section 6.2 below we address the case $T = J$ (which has the case $T = K$ as a corollary).

The following theorem (cf. Proposition 1 of [9]) shows how one can extract witnesses from proofs of Π_2^0 -statements in classical analysis via the J -translation and the J -shift (as opposed to via the negative translation and the double negation shift).

Theorem 5.2 *If*

$$\text{PA}^\omega + \text{AC}_{\mathbb{N}} + \text{DC}_{\mathbb{N}} \vdash \forall x^X \exists n^{\mathbb{N}} P(x, n)$$

then one can extract a term t in system $T + \text{ps}$ such that

$$\text{MA}^\omega + \text{BI} + \text{CONT} \vdash P(x, tx).$$

Proof By prefixing each atomic formula with a double negation, EFQ is eliminated. Hence the assumption of the theorem implies

$$\text{MA}^\omega + J_\perp\text{-elim} + \text{AC}_{\mathbb{N}} + \text{DC}_{\mathbb{N}} \vdash \forall x \exists n \neg\neg P(x, n).$$

Because the proof is in ML, we can replace \perp by any formula, which we take to be $R \equiv \exists n P(x, n)$

$$\text{MA}^\omega + J_R\text{-elim} + \text{AC}_{\mathbb{N}} + \text{DC}_{\mathbb{N}} \vdash \forall x \exists n ((P(x, n) \rightarrow R) \rightarrow R).$$

Hence,

$$\text{MA}^\omega + J_R\text{-elim} + \text{AC}_{\mathbb{N}} + \text{DC}_{\mathbb{N}} \vdash \forall x \exists n P(x, n).$$

By the J -translation we have

$$\text{MA}^\omega + \text{AC}_{\mathbb{N}}^J + \text{DC}_{\mathbb{N}}^J \vdash \forall x J \exists n J P(x, n),$$

and, by the choice of R we have $J \exists n J P(x, n) \rightarrow P(x, n)$. Therefore,

$$\text{MA}^\omega + \text{AC}_{\mathbb{N}}^J + \text{DC}_{\mathbb{N}}^J \vdash \forall x \exists n P(x, n).$$

We are now done because $\text{AC}_{\mathbb{N}}^J$ and $\text{DC}_{\mathbb{N}}^J$ follow, in $\text{MA}^\omega + \text{AC}_{\mathbb{N}} + \text{DC}_{\mathbb{N}}$, from J -shift, which, by Theorem 4.3, is realized by ps, and because $\text{AC}_{\mathbb{N}}$ and $\text{DC}_{\mathbb{N}}$ have simple modified realizability witnesses. \square

6. Full Dependent Choice

We have discussed how one normally interprets the axiom of *countable* choice computationally by reducing it to the computational interpretation of the double negation shift (cf. [3, 8, 9] and Theorem 5.2 above). When it comes to the computational interpretation of the *dependent* choice

$$\text{DC} \quad : \quad \forall n, x \exists y B_n(x, y) \rightarrow \forall x_0 \exists \alpha [\alpha 0 = x_0] \forall n B_n(\alpha n, \alpha(n+1)),$$

however, one normally does it directly, as it seems not possible to reduce the negative translation of DC using the simple double negation shift. In this section, continuing the discussion started in Section 4, we show that what is needed in order to approach this from a logical point of view is a *dependent* variant of the shift principle.

6.1. Weak dependent choice

We start our analysis, however, with the special case of the *weak dependent choice* wDC

$$\forall n^{\mathbb{N}} (\forall i < n \exists x^{X_i} A_i(x) \rightarrow \exists x^{X_n} A_n(x)) \rightarrow \exists \alpha \forall n A_n(\alpha(n)),$$

and the following generalisation of the J -shift, which we shall call the *course-of-values* J -shift,

$$J^r\text{-shift} \quad : \quad \forall n (\forall i < n A(i) \rightarrow JA(n)) \rightarrow J\forall n A(n).$$

It is easy to see that J^r -shift follows from J -shift by a simple application of induction. The next lemma shows that the J -translation of the weak dependent choice wDC can be reduced to the standard countable choice plus J^r -shift.

Lemma 6.1 $\text{AC}_{\mathbb{N}} + J^r\text{-shift} \vdash \text{wDC}^J$.

Proof wDC is ML equivalent to

$$\forall n (\exists s A(s) \rightarrow \exists x A_n(x)) \rightarrow \exists \alpha \forall n A_n(\alpha(n)),$$

where $A(s) = \forall i < |s| A(s_i)$. Let $B(n)$ be $\exists x A_n(x)$. Assume the premise of wDC^J , i.e.

$$\forall n (\forall i < n B(i) \rightarrow JB(n)).$$

By the course-of-values J -shift we have $J\forall n B(n)$, i.e. $J\forall n \exists x A_n(x)$. By $\text{AC}_{\mathbb{N}}$ we obtain the conclusion of wDC^J . \square

Theorem 6.2 ($\text{HA}^\omega + \text{BI} + \text{CONT}$) $\text{PS}_{\langle \rangle}$ mr J^r -shift.

We formulate and prove a stronger version of this in Theorem 6.4.

6.2. Full Dependent Choice

We can generalise wDC so that the witness for point n might depend on all witnesses A_i for $k < n$. Suppose A_n is a predicate on finite sequence $\prod_{k < n} X_k$, then

$$\text{DC}_{\text{seq}} : \forall s (\forall j < |s| A_j([s](j)) \rightarrow \exists x A_{|s|}(s * x)) \rightarrow \exists \alpha \forall n A_n([\alpha](n)),$$

which we call the *dependent choice* for finite sequences. DC_{seq} has also been used in [14, Section 2.3]. We argue now that DC_{seq} is the natural generalisation of the courser-of-values J -shift, discussed in Section 6. Consider the binary case of J^r -shift

$$JA(0) \wedge (A(0) \rightarrow JA(1)) \rightarrow J(A(0) \wedge A(1)).$$

First, suppose that each $A(n)$ is a predicate on finite sequences of length n , i.e. of the form $A(n) = \exists s^{\prod_{i < n} X_i} B_n(s)$. We then have

$$J\exists s B_0(s) \wedge (\exists s B_0(s) \rightarrow J\exists t B_1(t)) \rightarrow J(\exists s B_0(s) \wedge \exists t B_1(t)).$$

We are interested in the case when the finite sequence witnessing B_n is required to be an extension of a finite sequence witnessing B_i , for $i < n$,

$$J\exists s B_0(s) \wedge \forall s (B_0(s) \rightarrow J\exists x B_1(s * x)) \rightarrow J\exists t (B_0([t](0)) \wedge B_1([t](1))).$$

As it can be easily seen, the generalisation of this to infinite many predicates is precisely DC_{seq} . We first show that DC_{seq} is equivalent over MA^ω to the usual formulation of dependent choice.

Lemma 6.3 DC_{seq} and DC are equivalent over MA^ω .

Proof Let us first show how DC_{seq} can be used to prove the usual formulation of dependent choice. Consider

$$A_n(s) \equiv (|s| = n) \rightarrow \forall i < n B_i(s_i, s_{i+1}),$$

where $t = x_0 * s$. It is easy to show that the hypothesis $\forall n, x \exists y B_n(x, y)$ implies

$$\forall s (\forall i < |s| A_i([s](i)) \rightarrow \exists x A_{|s|}(s * x)).$$

Therefore, by DC_{seq} we get $\exists \alpha \forall n A_n([\alpha](n))$, which implies

$$\exists \alpha (\alpha(0) = x_0 \wedge \forall n B_n(\alpha(n), \alpha(n+1))).$$

For the other direction, assume a predicate $A_n(s)$ is given, such that the premise of DC_{seq} holds. Define

$$B_n(s, t) = (|s| = n) \wedge (|t| = n + 1) \wedge \forall i < n (s_i = t_i) \wedge A_{n+1}(t).$$

The assumed premise of DC_{seq} implies $\forall n \forall s \exists t B_n(s, t)$, which by DC gives

$$\forall x_0 \exists \alpha (\alpha(0) = x_0 \wedge \forall n B_n(\alpha(n), \alpha(n+1))).$$

Take x_0 arbitrary, and ignore B_0 . We then have

$$\exists \alpha \forall n B_{n+1}(\alpha(n), \alpha(n+1)).$$

Taking $\beta(i) = (\alpha(i+1))_i$ we have a witness for the conclusion of DC_{seq} . \square

Finally, we show that PS, which in Theorem 6.2 is shown to realize J^r -shift, also realizes the J -translation of DC_{seq} directly.

Theorem 6.4 ($\text{HA}^\omega + \text{BI} + \text{CONT}$) *Let R be a Σ_1^0 -formula. Then $\text{PS}_{\langle \rangle} \text{mr DC}_{\text{seq}}^J$.*

Proof Assume the realizer for $\exists y^{Y_n} A_n(s * y)$ has type $X_n(s) \equiv \Sigma_{y \in Y_n} Z_n(s * y)$. Moreover, assume we are given functionals ε and q such that

$$\begin{aligned} \varepsilon \quad \text{mr} \quad & \forall s (\forall i < |s| A_i([s](i)) \rightarrow J \exists y A_{|s|}(s * y)) \\ q \quad \text{mr} \quad & \exists \alpha \forall n A_n([\alpha](n)) \rightarrow R. \end{aligned}$$

Then ε and q have types

$$\prod_s \left(\prod_{i < |s|} Z_i([s](i)) \rightarrow J X_{|s|}(s) \right) \quad \text{and} \quad \sum_{\alpha \in \Pi_i Y_i} \prod_n Z_n([\alpha](n)) \rightarrow R,$$

respectively. We want to show that

$$\text{PS}_{\langle \rangle}(\varepsilon)(q) \text{mr } \exists \alpha \forall n A_n([\alpha](n)).$$

For a sequence of pairs $t: \prod_{i < n} (V_i \times W_i)$ we write $t^0: \prod_{i < n} V_i$ for the projection of the sequence on all first elements. In the following we let t range over the type $\prod_{i < n} X_i([t^0](i)) \equiv \prod_{i < n} \sum_{y \in Y_i} Z_i([t^0](i) * y)$. In words, t is a sequence of pairs where the first elements of each pair t^0 determine the type of the second elements of each pair. We prove $\forall t P(t)$ by relativised bar induction (cf. [9]), where

$$P(t) \equiv \text{PS}_t(\varepsilon)(q_t) \text{mr } \exists \alpha \forall n A_{|t|+n}(t^0 * [\alpha](n)).$$

The bar induction will be relativised to the predicate

$$Q(t) \equiv \forall i < |t| (t_i \text{mr } \exists y A_i([t^0](i) * y)).$$

The first hypothesis $Q(\langle \rangle)$ of the bar induction is vacuously true. We now prove the two remaining hypothesis (i) and (ii).

(i) $\forall \alpha^Q \exists k P([\alpha](k))$. Given α , pick k to be a point of continuity of q on α . We must show $P([\alpha](k))$, i.e.

$$\text{PS}_{[\alpha](k)}(\varepsilon)(q_{[\alpha](k)}) \text{ mr } \exists \beta \forall n A_{k+n}([\alpha](k))^0 * [\beta](n).$$

Let $\langle \gamma, \delta \rangle = \text{PS}_{[\alpha](k)}(\varepsilon)(q_{[\alpha](k)})$. The above follows from, for all n ,

$$(+) \delta(n) \text{ mr } A_{k+n}([\alpha](k))^0 * [\gamma](n),$$

which we establish by course-of-values induction as follows. Unfolding the definition of PS, (+) is equivalent to

$$(\varepsilon_{[\alpha](k)*r}(\lambda x. q_{[\alpha](k)*r*x}(\text{PS}_{[\alpha](k)*r*x}(\varepsilon)(q_{[\alpha](k)*r*x}))))_1 \text{ mr } A_{k+n}([\alpha](k))^0 * [\gamma](n),$$

where $r = [\text{PS}_{[\alpha](k)}(\varepsilon)(q_{[\alpha](k)})](n)$ and $x: X_{k+n}([\alpha](k) * r)$. By the fact that k is a point of continuity of q on α , this is equivalent to

$$(\varepsilon_{[\alpha](k)*r}(\lambda x. q_{[\alpha](k)*r*x}(\mathbf{0})))_1 \text{ mr } A_{k+n}([\alpha](k))^0 * [\gamma](n).$$

Hence, by the assumption on ε it remains to show that $[\alpha](k) * r \in Q$ and that

$$\lambda x. q_{[\alpha](k)*r*x}(\mathbf{0}) \text{ mr } \exists y^{Y_{k+n}} A_{k+n}([\alpha](k))^0 * [\gamma](n) * y \rightarrow R.$$

The first follows by the hypothesis of the course-of-values induction. The second follows from the assumptions on q since $[\alpha](k) * r \in Q$.

(ii) $\forall s^Q (\forall t, x(Q(s * t * x) \rightarrow P(s * t * x)) \rightarrow P(s))$. Let $s \in Q$ be given, and assume

$$(1) \forall t, x(Q(s * t * x) \rightarrow P(s * t * x)).$$

We must show $P(s)$, i.e.

$$\text{PS}_s(\varepsilon)(q_s) \text{ mr } \exists \alpha \forall n A_{|s|+n}(s^0 * [\alpha](n)).$$

Again let $\langle \gamma, \delta \rangle = \text{PS}_s(\varepsilon)(q_s)$. It is enough to show that

$$(\text{PS}_s(\varepsilon)(q_s)(n))_1 \text{ mr } A_{|s|+n}(s^0 * [\gamma](n)),$$

which, by the definition of PS is

$$(\varepsilon_{s*r}(\lambda x. q_{s*r*x}(\text{PS}_{s*r*x}(\varepsilon)(q_{s*r*x}))))_1 \text{ mr } A_{|s|+n}(s^0 * [\gamma](n)),$$

where $r = [\text{PS}_s(\varepsilon)(q_s)](n)$. This can be reduced to proving

$$(2) \lambda x. q_{s*r*x}(\text{PS}_{s*r*x}(\varepsilon)(q_{s*r*x})) \text{ mr } \exists y A_{|s|+n}(s^0 * [\gamma](n) * y) \rightarrow R.$$

Now, assume x is such that $Q(s * r * x)$. Then, by (1) we have, $P(s * r * x)$, i.e.

$$(3) \text{PS}_{s*r*x}(\varepsilon)(q_{s*r*x}) \text{ mr } \exists \alpha \forall n A_{|s*r*x|+n}((s * r * x)^0 * [\alpha](n)).$$

By the assumption on q we have that (3) implies (2), which concludes the proof. \square

Corollary 6.5 *If*

$$\text{PA}^\omega + \text{AC}_\mathbb{N} + \text{DC}_{\text{seq}} \vdash \forall x^X \exists n^\mathbb{N} P(x, n)$$

then one can extract a term t in system $T + \text{ps}$ such that

$$\text{HA}^\omega + \text{BI} + \text{CONT} \vdash P(x, tx).$$

Proof $\text{AC}_\mathbb{N}$ and DC_{seq} are modified-realizable in system T . The result follows because ps is inter-definable with PS (cf. [7]), and hence J^d -shift is modified-realizable in $T + \text{ps}$. \square

7. Weak König's Lemma

Weak König's lemma

$$\text{WKL} : \forall n \exists s^{\mathbb{B}^*} (|s| = n \wedge T(s)) \rightarrow \exists \alpha^{\mathbb{B}^\omega} \forall n T([\alpha](n)),$$

has been shown by the Reverse Mathematics programme [15] to be one of the most fundamental theorems in mathematics. Above $T(s)$ is assume to be a Π_1^0 predicate, and to be prefix-closed, i.e. $T(s * t) \rightarrow T(s)$. In this section we show that WKL follows rather directly from DC_{seq} of type \mathbb{B} for Π_1^0 formulas, and hence, its interpretation follows from the interpretation of DC_{seq} given above.

Lemma 7.1 $\Pi_1\text{-DC}_{\text{seq}}^{\mathbb{B}}$ *implies* WKL , *over* PA^ω .

Proof Given a Π_1 predicate $T(s)$ assumed to satisfy

$$(*) \forall n \exists s (|s| = n \wedge T(s))$$

we define another Π_1 predicate

$$A_n(s) = (|s| = n) \wedge \forall k \exists t (|t| = k \wedge T(s * t)).$$

Now, by classical logic, $(*)$ implies

$$\forall s (\forall j < |s| A_j([s](j)) \rightarrow A_{|s|}(s * 0) \vee A_{|s|}(s * 1)).$$

By DC_{seq} we have an α satisfying $\forall n A_n([\alpha](n))$, i.e.

$$\exists \alpha \forall n \forall k \exists t (|t| = k \wedge T([\alpha](n) * t)).$$

Taking $k = 0$ we obtain the conclusion of WKL . \square

In fact, it is easy to show that WKL in turn implies DC_{seq} for Π_1^0 formulas, meaning that these two principles are equivalent.

Lemma 7.2 *WKL implies $\Pi_1^0\text{-DC}_{\text{seq}}^{\mathbb{B}}$, over HA^ω .*

Proof For the other direction, given a Π_1 predicate $A_n(s)$, where $s: \mathbb{B}^*$, we define a Π_1 -tree as

$$T(s) = \forall i < |s| A_i([s](i)).$$

$T(s)$ is the prefix-closure of $A_n(s)$. Moreover, assuming $A_n(s)$ satisfies the premise of DC_{seq}

$$\forall s(\forall j < |s| A_j([s](j)) \rightarrow \exists x A_{|s|}(s * x))$$

one can show by induction that $T(s)$ satisfies the premise of WKL, i.e. the condition (*) of previous proof. By WKL we have $\exists \alpha \forall k T([\alpha](k))$, which by definition of $T(s)$ is

$$\exists \alpha \forall k \forall i < k A_i([\alpha](i)).$$

This clearly implies the conclusion of DC_{seq} . □

8. Concluding remarks

We have developed a proof translation based on the monad J , rather than the usual continuation monad K , and shown how to realize a corresponding J -shift principle. In terms of modified realizability the J -shift is more general than the K -shift, since we are able to produce realizers for J -shift for arbitrary formulas A , and not just formulas such that $\perp \rightarrow \exists x A$, as is the case with the double negation shift. We have also considered a dependent variant of the J -shift, and shown it directly interprets the axiom of dependent choice. It would also be interesting to investigate the benefits of using the J -translation in combination with the dialectica interpretation [16]

We plan to investigate the use of the product of selection functions for extraction of computational content from proofs involving countable/dependent choice, as done by Seisenberger [14] with modified bar recursion. Based on the experimental results and theoretical conjectures of [5, Section 8.10] and [17], we expect that the product of selection functions will give rise to more efficient computational extraction of witnesses.
